## Interaction of molecular nitrogen with free-electron-laser radiation

H. I. B. Banks, D. A. Little, J. Tennyson and A. Emmanouilidou \*

We compute molecular continuum orbitals in the single center expansion scheme. We then employ these orbitals to obtain molecular Auger rates and single-photon ionization cross sections to study the interaction of N<sub>2</sub> with Free-Electron-Laser (FEL) pulses. The nuclei are kept fixed. We formulate rate equations for the energetically allowed molecular and atomic transitions and we account for dissociation through additional terms in the rate equations. Solving these equations for different parameters of the FEL pulse, allows us to identify the most efficient parameters of the FEL pulse for obtaining the highest contribution of double core hole states (DCH) in the final atomic ion fragments. Finally we identify the contribution of DCH states in the electron spectra and show that the DCH state contribution is more easily identified in the photo-ionization rather than the Auger transitions.

### 1 Introduction

The development of X-ray free electron lasers (FELs)<sup>1</sup> has introduced new tools for imaging and exploring novel states of atoms and molecules.<sup>2,3</sup> Potential applications of FELs range from imaging biomolecules<sup>4–6</sup> to accurate modeling of laboratory and astrophysical plasmas. FEL driven processes in atoms and molecules include single-photon ionization and Auger processes. Sequential single-photon ionization processes occurring on a time scale that is faster than Auger decays lead to the formation of multiple inner-shell holes in atoms and molecules. In an Auger process a valence electron drops in to fill a core hole; the energy released allows another valence electron to escape to the continuum. The formation of double core hole (DCH) states in molecules is of particular interest for chemical analysis.<sup>7,8</sup> The energy required to remove a core electron depends upon the chemical environment of the site the electron is removed from rendering DCHs a sensitive spectroscopic tool for chemical analysis.

To understand the formation and detection of single core hole (SCH) and DCH states in molecules, one must explore the interplay of Auger and photo-ionization processes. There has been a significant amount of work on calculating the Auger rates and photo-ionization cross sections in atoms<sup>9–14</sup> and molecules.<sup>15–21</sup> Computing these rates for molecules is more challenging. The reason is that molecules do not have spherical symmetry and thus computing the molecular continuum orbital of the escaping electron is a complex task.

Previous molecular studies with FEL radiation include models where the molecule is treated as a combination of atoms.

Then, in these models, the Auger rates and the photo-ionization cross sections are computed for atomic transitions.<sup>22,23</sup> These atomic rates are then used to setup rate equations to describe molecular interactions with FEL radiation. In some instances dissociation is accounted for through additional terms in the rate equations.<sup>22,23</sup> For high photon energy FEL pulses interacting with N<sub>2</sub>, these models have been used to compute the yields of the final atomic ion fragments as well as the contribution of the DCH molecular states in the yields of the final atomic ions.<sup>22,23</sup> Very recently, new methods have been developed to describe molecular states with multiple holes and to compute molecular transitions following interaction with FEL radiation.<sup>24,25</sup> These new methods have been employed to compute the yields of the final molecular ion states as well as the contribution of SCH and DCH states in water for fixed nuclei.<sup>26</sup> The calculations in these studies were performed with atomic continuum orbitals rather than molecular ones. The use of atomic continuum orbitals is a good approximation when these models are employed to study molecular interactions with high photon energy FEL pulses.

Previous studies<sup>27,28</sup> have identified the time delay between subsequent PA steps, with PA consisting of a single-photon ionization (P) and an Auger decay (A), as well as the inter-nuclear distance at the time these steps take place. It has been shown in ref. 27 that when comparing laser pulses of the same intensity but of different duration, PA events take place at smaller inter-nuclear distances for the smaller duration laser pulses. Similarly, when comparing laser pulses of the same duration but of different intensity, PA events take place at smaller inter-nuclear distances for the higher intensity laser pulses.<sup>27</sup> Thus, for laser pulses of small pulse duration and of high intensity the molecular transitions at small inter-nuclear

Department of Physics and Astronomy, University College London, Gower Street,  
London WC1E 6BT, UK. E-mail: a.emmanouilidou@ucl.ac.uk

distances are important rendering the effect of the nuclear motion less important. In addition, it follows that the use of molecular continuum orbitals *versus* atomic continuum orbitals will result in more accurate results mostly for small duration and high intensity FEL pulses.

$N_2$  interacting with FEL pulses has been the subject of many experimental studies.<sup>27,29–32</sup> In these studies the yields of the final atomic ion states and the formation of molecular DCHs are investigated. In this work, we study the interaction of the  $N_2$  diatomic molecule with FEL radiation. To do so, we assume that the nuclei are fixed, an assumption also made in previous studies.<sup>22,23,26</sup> Very importantly, we compute the molecular continuum orbitals. We then employ these orbitals to compute the Auger rates and the single-photon ionization cross sections for all molecular transitions that are energetically accessible.

We investigate the interaction of a 525 eV and a 1100 eV FEL pulse with  $N_2$ . These photon energies are sufficient to create three inner-shell holes through sequential single-photon absorptions and multiple valence holes in the ground state of  $N_2$ . Moreover, as we show in the section concerning electron spectra, for a 525 eV FEL pulse some of the electrons ionize with very small energies. These small energies render necessary the use of molecular continuum orbitals, as is done in the current work. We compute the Auger and the single-photon ionization processes for the allowed molecular transitions, thus improving over previous studies that consider only atomic transitions.<sup>23</sup> We note that the use of molecular bound state orbitals is important for obtaining electron spectra. Indeed, it has been shown that with high-resolution electron spectroscopy one can observe the energy splitting of the molecular core hole states  $1\sigma_g$  and  $1\sigma_u$ .<sup>17,33</sup> We then set up rate equations for the allowed molecular and atomic transitions and account for dissociation through additional terms in the rate equations. We also investigate the dependence of the final molecular and atomic ion fragments on the intensity and pulse duration of the FEL pulse. We compare the atomic ion yields with experimental results<sup>23,32</sup> and find very good agreement. Moreover, we compute all energetically accessible pathways and can thus determine the contribution of the DCH molecular states in the final atomic ion states as well as in the electron spectra. Finally, we investigate whether photo-ionization or Auger transitions in the electron spectra are more effective in detecting the formation of DCH molecular states.

## 2 Ion yields and pathways

We study the response of  $N_2$  to FEL pulses of photon energies 525 eV and 1100 eV. We do so by formulating and solving a set of rate equations for the time dependent population of the ion states.

### 2.1 Rate equations

We construct rate equations for each energetically accessible state of molecular nitrogen. Each molecular state is denoted by its electronic configuration ( $1\sigma_g^a, 1\sigma_u^b, 2\sigma_g^c, 2\sigma_u^d, 1\pi_{ux}^e, 1\pi_{uy}^f, 3\sigma_g^g$ ) with a, b, c, d, e, f, g the number of electrons occupying a

Fig. 1 Ionization pathways between different electronic configurations of  $N_2$  up to  $N_2^{4+}$ , accessible with sequential single-photon ( $h\omega = 525$  eV) absorptions and Auger decays. The green and red lines indicate photo-ionization and Auger transitions, respectively.

molecular orbital. Each occupation number is equal to 0, 1 or 2. 2 corresponds to the maximum occupancy of a molecular orbital of two electrons with spin up and down. Atomic units are used in this work, unless otherwise stated. In Fig. 1, accounting for states up to  $N_2^{4+}$ , we illustrate the photo-ionization and Auger transitions between molecular states that are accessible due to the interaction of  $N_2$  with a 525 eV laser pulse. To create a core hole, a minimum photon energy of 420 eV is required. The transitions in Fig. 1 were calculated for the ground state equilibrium distance of the nuclei for  $N_2$ . This was done by employing Molpro<sup>34</sup> and performing a Hartree Fock calculation using correlation-consistent polarized triple-zeta (cc-pVTZ) basis set.

We assume that the nuclei are fixed at the equilibrium distance of  $N_2$  of 2.08 a.u. To model the fragmentation of  $N_2$  that leads to the formation of atomic ions, we include in the rate equations terms accounting for dissociation. Specifically, we assume that instantaneous dissociation, *i.e.* a very large dissociation rate, takes place from the  $N_2^{4+}$  and  $N_2^{3+}$  molecular states with no core holes. Dissociation of  $N_2^{3+}$  and  $N_2^{4+}$  leads to  $N^+ + N^{2+}$  and  $N^{2+} + N^{2+}$ , respectively. As in ref. 23, we further assume that all  $N_2^{2+}$  molecular states dissociate. We take the dissociation lifetime to be equal to 100 fs.<sup>35</sup> This is a reasonable assumption. It has been shown that only few non-dissociated molecules  $N_2^{2+}$  were detected in the experiment contributing less than 2% in the  $N^+$  peak of the final atomic ion fragments.<sup>32</sup>  $N_2^{2+}$  dissociation leads to  $N^+ + N^+$  and  $N + N^{2+}$  with probabilities 74% and 26%,<sup>35</sup> respectively. The above dissociation processes are similar to the dissociation processes taken into account in ref. 23. In the rate equations fluorescence is not accounted for since the corresponding rates are much smaller compared to Auger and single-photon ionization processes.<sup>36</sup> In the rate equations we also account for the states of atomic nitrogen that are accessible through molecular fragmentation and through single-photon ionization and Auger processes occurring in the atomic ion states. Each atomic state is denoted by

( $1s^a, 2s^b, 2p^c$ ) with a, b and c the occupation numbers of the atomic orbitals.

We formulate molecular rate equations to describe the population  $\mathcal{I}_j(t)$  of a molecular ion state j. In addition, we solve for the Auger  $\mathcal{A}_{i \rightarrow j}$  and the photo-ionization  $\mathcal{P}_{i \rightarrow j}$  yield from an initial molecular state i with charge  $q - 1$  to a final molecular state j with charge  $q$ . These yields provide the probability for observing an electron with energy corresponding to the molecular transition  $i \rightarrow j$ . We use these yields to describe the molecular transitions in the electron spectra produced by the interaction of  $N_2$  with an FEL pulse. The electron spectra are presented later in the paper. We also formulate rate equations to describe the population of an atomic state n. We also solve for the Auger  $\mathcal{A}_{m \rightarrow n}$  and the photo-ionization  $\mathcal{P}_{m \rightarrow n}$  yields from an initial atomic state m with charge  $q - 1$  to a final atomic state n with charge  $q$ . These yields provide the probability for observing an electron with energy corresponding to the atomic transition  $m \rightarrow n$ . We use these yields to describe the atomic transitions in the electron spectra produced by the interaction of  $N_2$  with an FEL pulse. It is also of interest to compute the population transfer through a specific pathway  $i \rightarrow j \rightarrow k$  where the initial state is i and the final one that is k is reached through the state j. Each pathway starts from the ground state of  $N_2$  and ends at an accessible atomic or molecular ion state. Obtaining the pathway populations allows to determine the percentage of final ion states that were formed through pathways involving molecular states with only a single or a double core hole. These results are presented later in the paper. For a detailed description of the rate equations, see Appendix A.

## 2.2 Electron continuum molecular orbitals

An advantage of the rate equations formulated in the previous section is that we compute the single-photon ionization cross sections and the Auger rates using the continuum wave functions of the molecular orbitals. We compute these continuum molecular orbitals by following the formulation in ref. 37. In what follows, we briefly outline the steps we follow to compute the continuum molecular orbitals. The first step in the derivation involves the Hartree–Fock equations<sup>38</sup> given by

$$\underbrace{-\frac{1}{2}\nabla^2\phi_\varepsilon(\mathbf{r})}_{\text{Kinetic energy}} + \underbrace{\sum_n^{\text{nuc.}} \frac{-Z_n}{|\mathbf{r}-\mathbf{R}_n|}\phi_\varepsilon(\mathbf{r})}_{\text{Electron-nuclei}} + \underbrace{\sum_i^{\text{orb.}} a_i \int d\mathbf{r}' \frac{\phi_i^*(\mathbf{r}')\phi_i(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\phi_\varepsilon(\mathbf{r})}_{\text{Direct interaction}} - \underbrace{\sum_i^{\text{orb.}} b_i \int d\mathbf{r}' \frac{\phi_i^*(\mathbf{r}')\phi_\varepsilon(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\phi_i(\mathbf{r})}_{\text{Exchange interaction}} = \varepsilon\phi_\varepsilon(\mathbf{r}) \quad (1)$$

The index  $\varepsilon$  denotes a continuum molecular orbital with  $\varepsilon > 0$  the energy of the ionizing electron. The index i denotes bound molecular orbitals, where  $a_i$  and  $b_i$  are coefficients associated with the orbital i. These coefficients are derived in Appendix B.  $\mathbf{R}_n$  denotes the position of nucleus n. The electron–nuclei term is the Coulomb interaction of the continuum

electron with each one of the nuclei. The direct and exchange terms arise from the Coulomb interaction of the continuum electron with the bound electrons. To simplify the numerical integrations involved in eqn (1), the bound and continuum orbital wave functions are expressed using the single-centre expansion (SCE).<sup>37</sup> This approximation allows for the angular part of the integrations in eqn (1) to be obtained analytically. According to the SCE the wave function of the molecular orbital i is expressed as

$$\phi_i(\mathbf{r}) = \sum_{lm} \frac{P_{lm}^i(r) Y_{lm}(\theta, \phi)}{r}, \quad (2)$$

with  $\mathbf{r} = (r, \theta, \phi)$  denoting the position of the electron. For continuum orbitals, i is replaced by the energy of the ionizing electron  $\varepsilon$ .  $Y_{lm}$  is a spherical harmonic with quantum numbers  $l$  and  $m$ .  $P_{lm}^i(r)$  are single centre expansion coefficients for the orbital i. Substituting eqn (2) in eqn (1) and then multiplying by  $Y_{lm}^*$  and integrating over the angular part results in

$$\sum_{l'm'} \left[ \left( -\frac{d^2}{dr^2} + \frac{l(l+1)}{r^2} - 2\varepsilon \right) \delta_{ll'} \delta_{mm'} + 2V_{lm,l'm'}^{\text{ne}}(r) + 2J_{lm,l'm'}^{\text{ce}}(r) \right] \times P_{l'm'}^e(r) - 2X_{lm}[\bar{P}^e](r) = 0. \quad (3)$$

$V_{lm,l'm'}^{\text{ne}}(r)$  is the electron–nuclei interaction,  $J_{lm,l'm'}^{\text{ce}}(r)$  is the direct interaction term, and  $X_{lm}[\bar{P}^e](r)$  is the exchange interaction term. In eqn (3), we are solving for  $P_{l'm'}^e(r)$ , which are the coefficients in the SCE of the continuum wavefunction.  $\bar{P}^e$  is the vector form of  $P_{l'm'}^e(r)$ . The electron–nuclei interaction  $V_{lm,l'm'}^{\text{ne}}(r)$  is given by

$$V_{lm,l'm'}^{\text{ne}}(r) = \sum_n^{\text{nuc.}} -Z_n(-1)^m \sqrt{(2l+1)(2l'+1)} \times \sum_{kq} \begin{pmatrix} l & k & l' \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} l & k & l' \\ -m & q & m' \end{pmatrix}, \quad (4)$$

$$\times \sqrt{\frac{4\pi}{2k+1}} Y_{kq}^*(\theta_n, \phi_n) \frac{r_{<}^k}{r_{>}^{k+1}}$$

with the angular integration expressed in terms of Wigner 3j-symbols;<sup>39</sup>  $r_{<} = \min(r, R_n)$  and  $r_{>} = \max(r, R_n)$ . The direct interaction  $J_{lm,l'm'}(r)$  is given by

$$J_{lm,l'm'}(r) = \sum_i a_i \sum_{l_2 m_2, l_3 m_3, kq} \sqrt{(2l+1)(2l'+1)(2l_2+1)(2l_3+1)} \times \begin{pmatrix} l_2 & k & l_3 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} l_2 & k & l_3 \\ -m_2 & q & m_3 \end{pmatrix} \begin{pmatrix} l' & k & l \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} l' & k & l \\ -m' & q & m \end{pmatrix} \times (-1)^{m_2+m'} \int_0^\infty \frac{r_{<}^k}{r_{>}^{k+1}} P_{l_2 m_2}^{i*}(r') P_{l_3 m_3}^i(r') dr', \quad (5)$$

where  $r_{<} = \min(r, r')$  and  $r_{>} = \max(r, r')$  and,  $l_2, m_2$  and  $l_3, m_3$  refer to the orbital i. The exchange interaction can be cast as a functional of

the SCE coefficients of the continuum electron orbital as follows

$$\begin{aligned}
 X_{lm}[\bar{P}^e](r) &= \sum_{l'm'}^{\text{orb.}} \sum_i b_i \sum_{l_2 m_2, l_3 m_3, l_4} \sqrt{(2l+1)(2l'+1)(2l_2+1)(2l_3+1)} \\
 &\times \begin{pmatrix} l_2 & k & l' \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} l_2 & k & l' \\ -m_2 & q & m' \end{pmatrix} \begin{pmatrix} l_3 & k & l \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} l_3 & k & l \\ -m_3 & q & m \end{pmatrix} \\
 &\times (-1)^{m_2+m_3} \int_0^\infty \frac{r^k}{r^{k+1}} P_{l_2 m_2}^{i*}(r') P_{l' m'}^e(r') dr' P_{l_3 m_3}^i(r). \quad (6)
 \end{aligned}$$

For numerical efficiency,  $P_{l'm'}^e(r)$  are obtained solving eqn (3) with the non-iterative method described in ref. 37. Diatomic molecules have rotational symmetry around the molecular axis and thus  $m$  is a good quantum number. Therefore,  $m_2$  and  $m_3$  are equal and have a fixed value for a bound orbital  $i$ . In addition,  $m$  and  $m'$  are equal and have a fixed value determined by the symmetry of the continuum orbital. For the  $N_2$  diatomic molecule, we find that convergence of the continuum orbital is achieved when considering  $l$  up to 19 for the single center expansion. As a result, for each energy  $\varepsilon$ , eqn (3) has at the most 20 degenerate solutions.

### 2.3 Photo-ionization cross-sections

The photo-ionization cross-section<sup>40</sup> for an electron transitioning from an initial molecular orbital  $\phi_i$  to a final continuum molecular orbital  $\phi_e$  is given by

$$\sigma_{i \rightarrow e} = \frac{4}{3} \alpha \pi^2 \omega N_i \sum_{M=-1,0,1} |D_{ie}^M|^2, \quad (7)$$

where  $\alpha$  is the fine structure constant,  $N_i$  is the occupation number of the initial molecular orbital  $i$ ,  $\omega$  is the photon energy, and  $M$  is the polarization of the photon. In the length gauge, the matrix element  $D_{ie}^M$  is given by

$$D_{ie}^M = \int \phi_i(r) \phi_e(r) \sqrt{\frac{4\pi}{3}} r Y_{1M}(\theta, \phi) dr. \quad (8)$$

In the single centre expansion formalism eqn (8) takes the form

$$\begin{aligned}
 D_{ie}^M &= \sqrt{\frac{4\pi}{3}} \sum_{lm, l'm'} \int_0^\infty dr P_{lm}^{i*}(r) r P_{l'm'}^e(r) \\
 &\times \int dW Y_{lm}^*(\theta, \phi) Y_{l'm'}(\theta, \phi) Y_{1M}(\theta, \phi) \\
 &= \sum_{lm, l'm'} (-1)^m \sqrt{(2l+1)(2l'+1)} \begin{pmatrix} l & l' & 1 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} l & l' & 1 \\ -m & m' & M \end{pmatrix} \\
 &\times \int_0^\infty dr P_{lm}^{i*}(r) r P_{l'm'}^e(r). \quad (9)
 \end{aligned}$$

We compare for several transitions in  $N_2$  the photo-ionization cross sections we compute using eqn (9) with previous calculations.<sup>41</sup> We find overall a very good agreement as shown for two transitions in Table 1. Differences between our results

**Table 1** Photo-ionization cross-sections for  $N_2$  transitions: columns 3 and 5 correspond to our results and columns 2 and 4 correspond to previous calculations<sup>41</sup>

$E_{\text{photon}}$ (eV)	$2\sigma_g \rightarrow \varepsilon\sigma_u$		$2\sigma_g \rightarrow \varepsilon\pi_u$	
	Ref. 41	This work	Ref. 41	This work

75	0.40	0.44	0.70	0.72
80	0.31	0.33	0.65	0.69

and the ones in ref. 41 might be due to the fact that in ref. 41 the Hartree-Fock equations are solved with  $a_i = 2$  and  $b_i = 1$  for all orbitals which is not the case in our calculations, see Appendix B.

### 2.4 Auger rates

In general, the Auger rate is given by<sup>42</sup>

$$\Gamma = \overline{\sum} 2\pi |\mathcal{M}|^2 \equiv \overline{\sum} 2\pi |\langle \Psi_{\text{fin}} | H_I | \Psi_{\text{init}} \rangle|^2, \quad (10)$$

where  $\overline{\sum}$  denotes a summation over the final states and an average over the initial states.  $|\Psi\rangle$  is the wavefunction of all electrons in the molecular state. In the Hartree-Fock approximation,  $|\Psi\rangle$  is given by a Slater determinant of one-electron spin-orbital wavefunctions. The Auger transition is treated as a two-electron process and therefore the relevant part of  $H_I$  is the electron-electron Coulomb interaction term. In the second quantization formalism,<sup>43,44</sup> this Hamiltonian term is given by

$$H_I^{\text{ec}} = \frac{1}{2} \sum_{\alpha\beta\gamma\delta} c_\alpha^\dagger c_\beta^\dagger c_\gamma c_\delta \left\langle \alpha\beta \left| \frac{1}{r_{12}} \right| \gamma\delta \right\rangle, \quad (11)$$

where  $c_\gamma$  is the annihilation operator of the one-electron spin-orbital wavefunction  $|\gamma\rangle$  and  $c_\alpha^\dagger$  is the creation operator of the one-electron spin-orbital wavefunction  $|\alpha\rangle$ . Then, the matrix element takes the form

$$\langle \Psi_{\text{fin}} | H_I^{\text{ec}} | \Psi_{\text{init}} \rangle_{\text{Auger}} = \frac{1}{2} \sum_{\alpha\beta\gamma\delta} \langle \Psi_{\text{fin}} | c_\alpha^\dagger c_\beta^\dagger c_\gamma c_\delta | \Psi_{\text{init}} \rangle \left\langle \alpha\beta \left| \frac{1}{r_{12}} \right| \gamma\delta \right\rangle. \quad (12)$$

Using the anti-commutation relations of the creation and annihilation operators, eqn (12) is written as

$$\langle \Psi_{\text{fin}} | H_I^{\text{ec}} | \Psi_{\text{init}} \rangle_{\text{Auger}} = \left\langle \zeta s \left| \frac{1}{r_{12}} \right| ba \right\rangle - \left\langle \zeta s \left| \frac{1}{r_{12}} \right| ab \right\rangle. \quad (13)$$

In the Auger transition matrix element,  $a$  and  $b$  are the one-electron wavefunctions of the two valence electrons, while  $s$  and  $\zeta$  are the one-electron wavefunctions of the core and continuum electrons, respectively. In this transition, the core hole in spin-orbital  $s$  is filled by an electron from spin-orbitals  $a$  or  $b$ , while the other valence electron ionizes. Changing from the  $m_a \mu_a m_b \mu_b$

to the  $m_a m_b S M_S$  scheme we obtain

$$\begin{aligned} \mathcal{M} &= \langle \Psi_{\text{fin}} | H_1^{\text{cc}} | \Psi_{\text{init}} \rangle_{\text{Auger}} \\ &= \delta_{S',S} \delta_{M_S',M_S} \left( \left( \zeta_S \left| \frac{1}{r_{12}} \right| ba \right) + (-1)^S \left( \zeta_S \left| \frac{1}{r_{12}} \right| ab \right) \right). \end{aligned} \quad (14)$$

$m_a$  and  $\mu_a$  are the projection of the orbital angular momentum and spin, respectively, while  $S$  is the total spin and  $M_S$  is the projection of the total spin.  $\left( \zeta_S \left| \frac{1}{r_{12}} \right| ba \right)$  is the spatial part of the matrix element  $\left\langle \zeta_S \left| \frac{1}{r_{12}} \right| ba \right\rangle$  which is given by

$$\left( \zeta_S \left| \frac{1}{r_{12}} \right| ba \right) = \int d\mathbf{r} \phi_{\zeta}^* \phi_S^* \frac{1}{r_{12}} \phi_b \phi_a. \quad (15)$$

Using eqn (14) and (15) and expressing the orbital wavefunctions in the SCE scheme, we find

$$\begin{aligned} \mathcal{M} &= \delta_{S,S'} \delta_{M_S,M_S'} \\ &\times \left( \sum_{\substack{k'l'_s \\ l_b l_a}} \sum_{q=-k}^k \int d\mathbf{r}_1 \int d\mathbf{r}_2 P_{l'_s m'_s}^{*k} (r_1) P_{l_s m_s}^{*k} (r_2) \frac{r_{<}^k}{r_{>}^{k+1}} P_{l_b m_b}^b (r_1) P_{l_a m_a}^a (r_2) \right. \\ &\times (-1)^{m_s} \sqrt{(2l_s+1)(2l_a+1)} \begin{pmatrix} l_s & k & l_a \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} l_s & k & l_a \\ -m_s & q & m_a \end{pmatrix} \\ &\times (-1)^{q+m'_s} \sqrt{(2l'_s+1)(2l_b+1)} \begin{pmatrix} k & l'_s & l_b \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} k & l'_s & l_b \\ -q & -m'_s & m_b \end{pmatrix} \\ &+ (-1)^S \sum_{\substack{k'l'_s \\ l_b l_a}} \sum_{q=-k}^k \int d\mathbf{r}_1 \int d\mathbf{r}_2 P_{l'_s m'_s}^{*k} (r_1) P_{l_s m_s}^{*k} (r_2) \frac{r_{<}^k}{r_{>}^{k+1}} P_{l_b m_b}^b (r_1) P_{l_a m_a}^a (r_2) \\ &\times (-1)^{m_s} \sqrt{(2l_s+1)(2l_b+1)} \begin{pmatrix} l_s & k & l_b \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} l_s & k & l_b \\ -m_s & q & m_b \end{pmatrix} \\ &\left. \times (-1)^{q+m'_s} \sqrt{(2l'_s+1)(2l_a+1)} \begin{pmatrix} k & l'_s & l_a \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} k & l'_s & l_a \\ -q & -m'_s & m_a \end{pmatrix} \right) \end{aligned} \quad (16)$$

where  $r_{<} = \min(r, r')$  and  $r_{>} = \max(r, r')$ . The Auger rate is given by

$$\Gamma_{b,a \rightarrow s, \zeta} = \sum_{\substack{m_a m_b m_s m'_s \\ S M_S S' M_S'}} \pi N_{12} N_h \sum_L |\mathcal{M}|^2, \quad (17)$$

with  $N_h$  the number of holes in the orbital to be filled.  $N_{12}$  is the weighting occupation factor given by

$$N_{12} = \begin{cases} \frac{N_{v1} N_{v2}}{2 \times 2} & \text{for different orbitals} \\ \frac{N_{v1}(N_{v1}-1)}{2 \times 2 \times 1} & \text{for same orbital} \end{cases} \quad (18)$$

where  $N_{v1}$  and  $N_{v2}$  are the occupations numbers of the valence orbitals that are involved in the Auger transition.

Next, we compare our results for the Auger rates of  $N_2^+$  with a 1s core-hole, which are computed using eqn (17) with the Auger rates calculated using a Green's function method.<sup>45</sup> The 1s state corresponds to  $\phi_{1s} = \frac{1}{\sqrt{2}}(\phi_{1\sigma_g} + \phi_{1\sigma_u})$ . Using the orthogonality of the molecular states, it follows that the 1s Auger rates are obtained by averaging the Auger rates of the  $1\sigma_g$  and  $1\sigma_u$  core hole molecular states. In the work in ref. 45, only relative values of the Auger rates are given. Specifically, the ratio of each Auger rate with respect to the transition is given. To compare the results in ref. 45 with our values we divide each Auger transition by the sum of all Auger transitions for a 1s core-hole state. The resulting values are shown in Table 2 and the agreement is shown to be overall good. The agreement between some of the Auger rates we compute in the current work and the Auger rates in ref. 45 is not as good. We believe this is due to the different techniques employed to compute the Auger rates. This is supported by further comparing Auger rates computed in the current work with results for Auger rates given in ref. 45 and 46. In the latter work, the author employs a Configuration Interaction calculation to compute the Auger rates of  $N_2^+$  with a 1s core hole. As in ref. 45, in ref. 46 only relative values of the Auger rates are given. In Table 3 we compare the ratio of some 1s Auger rates with the Auger rate for the transition to the  $^1\Sigma_g^+(3\sigma_g 3\sigma_g)$  state with 3 electrons filling in the core hole and being ejected to the continuum; we denote this final state by  $^1\Sigma_g^+(3\sigma_g 3\sigma_g)$ . We find that any two techniques agree only for some of the transitions shown in Table 3.

In addition, in Table 4 we compare our values with the experimental and theoretical results in ref. 17 for the Auger transitions from the  $1\sigma_g$  and the  $1\sigma_u$  core hole molecular states of  $N_2^+$  to the  $^1\Sigma_g^+(3\sigma_g3\sigma_g)$  and  $^1\Sigma_u^+(2\sigma_u3\sigma_g)$  states. We find a very good agreement, while the agreement between the results in ref. 45 and 46 with ref. 17 is not as good. Moreover, we find that the sum of all Auger rates corresponding to a  $1s$  core-hole is equal to  $2.87 \times 10^{-3}$  a.u. This value compares well with the experimental value of  $3.77 \times 10^{-3}$  a.u. obtained in ref. 29. We note that the Auger rates we use to solve the rate equations are summed over all allowed spin configurations. The reason for this is that spin is not specified in the electronic configurations of the molecular states.

### 3 Results

Using the methods described in the previous sections, we compute the photo-ionization cross sections and the Auger transitions for all allowed molecular transitions up to  $N_2^{4+}$  for 525 eV and 1100 eV FEL pulses.  $N_2^{4+}$  is the highest molecular ion state that can be reached, since we assume that the  $N_2^{4+}$  state dissociates instantaneously. In addition, using the method we developed in ref. 10 we compute the Auger rates for all allowed atomic transitions while we obtain the atomic single-photon ionization cross sections from ref. 47. We solve 309 rate equations to obtain the ion yields and the electron spectra. In addition, in order to obtain the population of all accessible pathways, we solve roughly  $1.8 \times 10^6$  rate equations for the 525 eV FEL pulse and  $6.6 \times 10^6$  rate equations for the 1100 eV FEL pulse. The computation of the pathway population allows us to identify the percentage of the contribution of SCH *versus* DCH molecular states to the final atomic ion yields.

#### 3.1 Ion yields

First, we compute the molecular and atomic ion yields for a 525 eV and a 1100 eV FEL pulses. For each photon energy we consider two different full width half maximum (FWHM) durations of the FEL pulse, namely 4 fs and 80 fs. In Fig. 2, we show the dependence on intensity of the molecular ion yields resulting from the interaction of  $N_2$  with four different FEL pulses. We find that only the  $N_2$  and  $N_2^+$  states are populated a long time after the end of the FEL pulses. This is expected, since, in our model, all higher charged states eventually dissociate. We also find that after a certain intensity the population of both the

**Fig. 2** Molecular ion yields resulting from the interaction of  $N_2$  with four FEL pulses as a function of the intensity of the laser pulse. For instance, a molecular ion yield of 0.1 for  $N_2$  means that 10% of all  $N_2$  molecules that interact with the laser pulse remain neutral while 90% ionize.

$N_2$  and the  $N_2^+$  molecular states reduces significantly for all four FEL pulses considered. For the same photon energy FEL pulses,  $N_2$  and  $N_2^+$  are depleted at a smaller intensity for the 80 fs FEL-pulse compared to the 4 fs one. Comparing the molecular ion yields of FEL pulses with the same FWHM but different photon energy, we find that depletion of  $N_2$  and  $N_2^+$  occurs at a smaller intensity for the 525 eV FEL pulse. The reason for this is that the single-photon ionization cross sections for the molecular transitions, are larger for the 525 eV FEL pulse compared to the 1100 eV FEL pulse, for a certain intensity. It is important to note that  $N_2^{2+}$  states are not plotted in Fig. 2, since we assume that all  $N_2^{2+}$  states dissociate. However, experimentally it is found that  $N_2^{2+}$  contributes roughly 2% of the  $N^+$  atomic ion yield. This experimental finding combined with the results we present for the atomic ion yields in Fig. 3 allows us to estimate that the contribution of  $N_2^{2+}$  is of the order of magnitude of  $N_2^+$  that is presented in Fig. 2.

Next, in Fig. 3 we show the atomic ion yields for the same four FEL pulses as in Fig. 2 as a function of the laser intensity. Comparing the atomic ion yields of FEL pulses with the same photon energy but different FWHM, we find that the population of the higher charged states becomes significant at smaller intensities for the 80 fs FEL pulse compared to the 4 fs one. This is expected. A longer pulse with the same intensity means more photons per pulse than in a shorter pulse with the same intensity. Since it is not the intensity but the fluence that matters for single-photon ionization, the longer pulse will result in more ionization. Next, we compare the atomic ion yields of FEL pulses with the same FWHM but different photon energy. We find that the population of the higher charged states becomes significant at smaller intensities for the 525 eV FEL pulse compared to the 1100 eV one. The reason for this is that the single-photon ionization cross sections both for the atomic and the molecular transitions are higher for the 525 eV FEL pulse.

Fig. 3 Atomic ion yields resulting from the interaction of  $N_2$  with four FEL pulses as a function of the intensity of the laser pulse.

### 3.2 Comparison of atomic ion yields with experiment

To compare the ion yields of the final fragments with the experimental results in ref. 32, we take the FEL flux to be given by

$$J(x, y, t) = \rho(x, y) \Gamma_{\text{ph}}(t), \quad (19)$$

where the transverse beam profile is given by

$$\rho(x, y) = \frac{4 \ln 2}{\pi \rho_x \rho_y} e^{-4 \ln 2 \left[ \left( \frac{x}{\rho_x} \right)^2 + \left( \frac{y}{\rho_y} \right)^2 \right]} \quad (20)$$

with  $\rho_x = 2.2 \mu\text{m}$  and  $\rho_y = 1.2 \mu\text{m}$  in accord with the experimental parameters in ref. 32. The temporal profile for the rate of photons is given by

$$\Gamma_{\text{ph}}(t) = \Gamma_{\text{ph},0} e^{-4 \ln 2 \left( \frac{t}{\tau} \right)^2}, \quad (21)$$

where  $\Gamma_{\text{ph},0}$  is the maximum rate of photons

$$\Gamma_{\text{ph},0} = 2 \sqrt{\frac{\ln 2}{\pi}} \frac{n_{\text{ph}}}{\tau} \quad (22)$$

with  $n_{\text{ph}} = \frac{E_{\text{p}}}{\omega}$  being the number of photons in a pulse with energy  $E_{\text{p}}$ , where each photon has photon energy  $\omega$ .  $\tau$  is the full width at half maximum (FWHM) of the duration of the laser pulse. We note that we also multiply the pulse energy by a factor

which accounts for the photon beam transport losses. The above analytic expression for the flux is also adopted in ref. 23. Computing the flux at different grid ( $x, y$ ) points, we then solve the rate equations at each grid point and integrate over an area of  $10 \mu\text{m} \times 10 \mu\text{m}$  to obtain the final ion yields. In Fig. 4, we show the atomic ion yields we obtain for pulse durations of 4 fs, 7 fs and 80 fs. We find that our results are in very good agreement with the experimental results presented in ref. 23 and 32.

### 3.3 Single versus double core holes

We now compute all energetically accessible pathways that start from the  $N_2$  ground state and end at ion fragments up to  $N^{7+}$  for a 4 fs FEL pulse. We identify the contribution to the atomic ion yields of pathways that have accessed only a SCH molecular state versus pathways that have accessed a DCH molecular state. This contribution is shown in Fig. 5 for a 525 eV and a 1100 eV FEL pulse at different laser pulse intensities.

First, we compare the results for two FEL pulses that have the same intensity of  $10^{17} \text{W cm}^{-2}$  but different photon energy, see Fig. 5(a) and (c). We find that the population of the higher charged atomic ion states is much larger for the 525 eV FEL pulse. The reason for this is that the molecular and atomic photo-ionization cross sections as well as the photon flux are larger for the 525 eV FEL pulse. Another consequence of the larger molecular photo-ionization cross sections is that for the

Fig. 4 Atomic ion yields for FEL pulses of (a) pulse energy 0.15 mJ with 4 fs FWHM and 77% loss (b) pulse energy 0.26 mJ with 7 fs FWHM and 84% loss (c) pulse energy 0.26 mJ with 80 fs FWHM and 70% loss. Our results are compared with experimental results.<sup>23,32</sup>

525 eV FEL pulse it is more probable for a second core hole to be created by single-photon ionization before an Auger transition takes place. This explains why the DCH molecular states contribute significantly more than the SCH molecular states to the population of the higher charged atomic ions, see Fig. 5(c). However, if a smaller intensity of  $10^{16} \text{ W cm}^{-2}$  is considered for the 525 eV FEL pulse, see Fig. 5(d), then similar results are obtained as for the 1100 eV FEL pulse at an intensity of  $10^{17} \text{ W cm}^{-2}$ , see Fig. 5(a). In Fig. 5(b), it is shown that when a higher intensity of  $10^{18} \text{ W cm}^{-2}$  is considered for the 1100 eV FEL pulse, similar results are obtained as for the 525 eV FEL at a smaller intensity, see Fig. 5(c). That is, higher charged atomic ion states are significantly populated and the DCH molecular states contribute significantly to these yields. The reason for this is that the higher intensity counteracts the effects from the single-photon ionization cross sections being smaller for the 1100 eV FEL pulse compared to the 525 eV FEL pulse.

Focusing on the 525 eV FEL pulse at an intensity of  $10^{17} \text{ W cm}^{-2}$ , we now explain in detail the contribution of the DCH molecular states to the charged atomic ions, see Fig. 5(c). In Table 5 we show the dominant pathways leading to the formation of the

atomic ions  $\text{N}$ ,  $\text{N}^+$ ,  $\text{N}^{2+}$ ,  $\text{N}^{3+}$  and  $\text{N}^{4+}$ . We find that the dominant pathways for the formation of  $\text{N}$  and  $\text{N}^+$  consist of a single-photon ionization from a core orbital  $\text{P}_C$  followed by an Auger decay from valence electrons  $\text{A}_{\text{VV}}$  or from a core hole and a valence electron  $\text{A}_{\text{CV}}$ . This  $\text{P}_C\text{A}_{\text{VV}}$  sequence is then followed by dissociation ( $D$ ) of  $\text{N}_2^{2+}$ . Thus,  $\text{N}$  and  $\text{N}^+$  are formed mostly by a molecular pathway that does not access DCH states.  $\text{N}^{2+}$ ,  $\text{N}^{3+}$  and  $\text{N}^{4+}$  are formed by dissociation of predominantly  $\text{N}_2^{4+}$ .  $\text{N}_2^{4+}$  is reached mostly through a molecular pathway that consists of a  $\text{P}_C\text{P}_C$  step, one  $\text{A}_{\text{VV}}$  event and one  $\text{A}_{\text{CV}}$  or  $\text{A}_{\text{VV}}$  or  $\text{P}_C$  event in all sequences that are energetically allowed denoted by  $\{\text{P}_C\text{P}_C + \text{A}_{\text{VV}} + \text{A}_{\text{CV}}/\text{A}_{\text{VV}}/\text{P}_C\}$ . All these latter pathways access DCH molecular states ( $\text{P}_C\text{P}_C$  step). However, dissociation of  $\text{N}_2^{4+}$  that has only valence holes plays a significant role in the formation of  $\text{N}^{2+}$  and  $\text{N}^{4+}$ . Indeed, the molecular pathway  $\text{P}_C\text{A}_{\text{VV}}\text{P}_C\text{A}_{\text{VV}}$  contributes 21% to the formation of  $\text{N}^{2+}$  and 9% to the formation of  $\text{N}^{4+}$ . This is not the case for  $\text{N}^{3+}$ . Thus the contribution of DCH molecular states to the formation of  $\text{N}^{3+}$  is larger than the contribution to the formation of  $\text{N}^{4+}$ .

### 3.4 Electron spectra

Using the molecular and atomic Auger and photo-ionization yields, we plot the probability for an electron to ionize with a certain energy, that is, we plot the electron spectra in Fig. 6. Specifically, we plot the electron spectra for 525 eV and 1100 eV FEL pulses at an intensity of  $10^{17} \text{ W cm}^{-2}$ . For each photon energy two FWHM laser pulses are considered, namely of 4 fs and of 80 fs. Comparing the electron spectra corresponding to the same FWHM FEL pulse, *i.e.* Fig. 6(a) with Fig. 6(c) and Fig. 6(b) with Fig. 6(d),

Fig. 5 Atomic ion yields for FEL pulses with 4 fs FWHM and photon energy of 525 eV and of 1100 eV.

Table 5 The % contribution to the atomic ion yields up to  $\text{N}^{4+}$  of the dominant pathways of ionization for a 4 fs FWHM, 525 eV photon energy and an intensity of  $10^{17} \text{ W cm}^{-2}$  FEL pulse. The pathway before the dissociation  $D$  is the molecular pathway of ionization

$\text{N}$	$\text{P}_C\text{A}_{\text{VV}}\text{D}$	94%
$\text{N}^+$	$\text{P}_C\text{A}_{\text{VV}}\text{D}$	85%
$\text{N}^{2+}$	$\{\text{P}_C\text{P}_C + \text{A}_{\text{VV}} + \text{A}_{\text{CV}}/\text{A}_{\text{VV}}/\text{P}_C\}\text{D}$	62%
$\text{N}^{2+}$	$\text{P}_C\text{A}_{\text{VV}}\text{P}_C\text{A}_{\text{VV}}\text{D}$	21%
$\text{N}^{3+}$	$\{\text{P}_C\text{P}_C + \text{A}_{\text{VV}} + \text{A}_{\text{CV}}/\text{A}_{\text{VV}}/\text{P}_C\}\text{DA}_{\text{VV}}$	79%
$\text{N}^{4+}$	$\{\text{P}_C\text{P}_C + \text{A}_{\text{VV}} + \text{A}_{\text{CV}}/\text{A}_{\text{VV}}/\text{P}_C\}\text{D}\{\text{P}_C/\text{A}_{\text{VV}} + \text{A}_{\text{VV}}\}$	73%
$\text{N}^{4+}$	$\text{P}_C\text{A}_{\text{VV}}\text{P}_C\text{A}_{\text{VV}}\text{DP}_C\text{A}_{\text{VV}}$	9%

Fig. 6 Electron spectra resulting from the interaction of  $N_2$  with FEL pulses at an intensity of  $10^{17} \text{ W cm}^{-2}$ .

we find that there is a higher contribution of atomic transitions to the electron spectra for the 525 eV FEL pulse. As previously mentioned, the reason is that the molecular photo-ionization cross sections are larger for the smaller photon energy resulting in a larger population reaching higher charged molecular states which in turn dissociate into atomic ion fragments. The atomic photo-ionization cross sections are also higher for the 525 eV FEL pulse and so higher charged atomic ion states are thus reached. Moreover, comparing the electron spectra corresponding to the same photon energy FEL pulse, *i.e.* Fig. 6(a) with Fig. 6(b) and Fig. 6(c) with Fig. 6(d) we find that there is a higher contribution of atomic transitions to the electron spectra for the longer duration, 80 fs, FEL pulse. The longer pulse duration allows for a larger number of photo-ionization processes to take place which in turn leads to the production of more higher charged atomic ion states. We also note that for the 525 eV FEL pulse the electrons can escape with small energies and that single-photon molecular transitions play an important role, see inset in Fig. 6(c). Thus, the formulation of the Auger and of the photo-ionization rates using molecular and not atomic continuum orbitals is more important for small photon energies and for small duration laser pulses.

We now investigate whether studying electron spectra is an efficient way of detecting the formation of DCH molecular states. To answer this question we plot the contribution to the Auger and photo-ionization yields of DCH molecular states.

We find that the contribution to the electron spectra of DCH Auger molecular transitions is difficult to distinguish and overlaps with Auger atomic transitions. However, the DCH single-photon ionization molecular transitions are easier to distinguish. For instance there is a clear peak in the electron spectra due to DCH single-photon ionization molecular transitions at around 55 eV for the case of the 525 eV 4 fs FEL pulse. This result confirms that photoionization electron spectra is a viable route for the detection of DCH molecular transitions as already implied by the large number of photoelectron studies.<sup>48–51</sup>

## 4 Conclusions

We investigate the interaction of molecular nitrogen with FEL radiation. We compute molecular continuum orbitals in the single center expansion scheme and use these orbitals to compute the Auger rates and photo-ionization cross-sections for molecular nitrogen. Formulating rate equations for all energetically accessible molecular and atomic transitions, we investigate the dependence of the final fragments yields on the parameters of the FEL pulse. Moreover, we study the contribution of the DCH molecular states to the final atomic ion yields. We find that for a relatively small photon energy of 525 eV, with 420 eV being the photon energy needed to create a core hole, already at intermediate intensities, DCH molecular states contribute

significantly to the formation of the final atomic ion fragments. Finally, we compute the contribution of the Auger and the single-photon ionization processes in the electron spectra. Our results suggest that single-photon ionization processes are a more efficient tool for detecting the formation of DCH molecular states in the electron spectra in agreement with previous experimental studies. Future studies will address in detail the effect of nuclear motion.

## Appendix

### A Rate equations

The rate equations describing the population  $\mathcal{I}_j(t)$  of a molecular ion state  $j$  take the form

$$\begin{aligned} \frac{d}{dt}\mathcal{I}_j(t) &= \sum_i (\sigma_{i \rightarrow j} J(t) + \Gamma_{i \rightarrow j}) \mathcal{I}_i(t) \\ &\quad - \sum_k (\sigma_{j \rightarrow k} J(t) + \Gamma_{j \rightarrow k}) \mathcal{I}_j(t) - \sum_n \kappa_{j \rightarrow n,p} \mathcal{I}_j(t), \\ \frac{d}{dt}\mathcal{A}_{i \rightarrow j} &= \Gamma_{i \rightarrow j} \mathcal{I}_i(t), \\ \frac{d}{dt}\mathcal{P}_{i \rightarrow j} &= \sigma_{i \rightarrow j} J(t) \mathcal{I}_i(t). \end{aligned} \quad (23)$$

$\sigma_{i \rightarrow j}$  and  $\Gamma_{i \rightarrow j}$  are the molecular single-photon absorption cross section and Auger decay rate, respectively, from the initial molecular state  $i$  to the final molecular state  $j$ .  $J(t)$  is the photon flux at time  $t$ . The temporal form of the FEL flux is modeled with a Gaussian function given by<sup>52</sup>

$$J(t) = 1.554 \times 10^{-16} \frac{I_0 [\text{W cm}^{-2}]}{\hbar\omega [\text{eV}]} \exp\left\{-4 \ln 2 \left(\frac{t}{\tau}\right)^2\right\} \quad (24)$$

with  $\tau$  the full width at half maximum (FWHM) and  $I_0$  the peak intensity. The molecular states  $i, j$  and  $k$  have charges  $q-1, q$  and  $q+1$ , respectively.  $\kappa_{j \rightarrow n,p}$  denotes the dissociation rate from the initial molecular state  $j$  with charge  $q$  to the final atomic states  $n$  and  $p$ . The atomic states  $n$  and  $p$  have total charge equal to  $q$ . For the dissociation cases currently considered, for each atomic final fragment  $n$  there is only one atomic final fragment  $p$ . The first term in eqn (23) accounts for the formation of the molecular state  $j$  through the single-photon ionization and Auger decay of the molecular state  $i$ . The second term in eqn (23) accounts for the depletion of the molecular state  $j$  by transitioning to a molecular state  $k$  through single-photon ionization and Auger decay. The third term accounts for the depopulation of the molecular state  $j$  through dissociation to the atomic states  $n$  and  $p$ . These rate equations, eqn (23), are used to calculate the molecular ion yields. In addition, in eqn (23), we solve for the Auger  $\mathcal{A}_{i \rightarrow j}$  and the photo-ionization  $\mathcal{P}_{i \rightarrow j}$  yield from an initial molecular state  $i$  with charge  $q-1$  to a final molecular state  $j$  with charge  $q$ .

The rate equations describing the populations of an atomic state  $n$  take the form

$$\begin{aligned} \frac{d}{dt}\mathcal{I}_n(t) &= \sum_m (\sigma_{m \rightarrow n} J(t) + \Gamma_{m \rightarrow n}) \mathcal{I}_m(t) \\ &\quad - \sum_o (\sigma_{n \rightarrow o} J(t) + \Gamma_{n \rightarrow o}) \mathcal{I}_n(t) + \sum_j \frac{\kappa_{j \rightarrow n,p}}{2 - \delta_{n,p}} \mathcal{I}_j(t), \\ \frac{d}{dt}\mathcal{A}_{m \rightarrow n} &= \Gamma_{m \rightarrow n} \mathcal{I}_m(t), \\ \frac{d}{dt}\mathcal{P}_{m \rightarrow n} &= \sigma_{m \rightarrow n} J(t) \mathcal{I}_m(t), \end{aligned} \quad (25)$$

where the indices  $n, m$  and  $o$  refer to atomic states with charges,  $q, q-1$  and  $q+1$ , respectively, while  $j$  refers to molecular states. The first term in eqn (25) accounts for the formation of the atomic state  $n$  through the single-photon ionization and Auger decay of the atomic state  $m$ . The second term in eqn (25) accounts for the depletion of the atomic state  $n$  by transitioning to an atomic state  $o$  through single-photon ionization and Auger decay. The third term in eqn (25) accounts for the population of state  $n$  as a result of dissociative transitions from a molecular state  $j$ . The factor  $\frac{1}{2 - \delta_{n,p}}$  conserves the population transfer from the molecular state  $j$ . Namely, if the molecular state results in the same two atomic fragments the factor is equal to 1. If fragmentation results in two different atomic fragments the factor is equal to  $\frac{1}{2}$ , since a rate equation is formulated for each atomic fragment separately. As in the molecular rate equations, in eqn (25), we solve for the Auger  $\mathcal{A}_{m \rightarrow n}$  and the photo-ionization  $\mathcal{P}_{m \rightarrow n}$  yields from an initial atomic state  $i$  with charge  $q-1$  to a final atomic state  $j$  with charge  $q$ . We note that eqn (23) and eqn (25) are solved simultaneously. We obtain the molecular and atomic ion yields long after the end of the laser pulse.

The three types of rate equations used to compute the population through a specific pathway  $i \rightarrow j \rightarrow k$  are given by eqn (26)–(28)

$$\begin{aligned} \frac{d}{dt}\mathcal{I}_{i \rightarrow j \rightarrow k}(t) &= (\sigma_{j \rightarrow k} J(t) + \Gamma_{j \rightarrow k}) \mathcal{I}_{i \rightarrow j}(t) \\ &\quad - \sum_l (\sigma_{k \rightarrow l} J(t) + \Gamma_{k \rightarrow l}) \mathcal{I}_{i \rightarrow j \rightarrow k}(t) \\ &\quad - \sum_n \kappa_{k \rightarrow n,p} \mathcal{I}_{i \rightarrow j \rightarrow k}(t), \end{aligned} \quad (26)$$

$$\begin{aligned} \frac{d}{dt}\mathcal{I}_{i \rightarrow j \rightarrow n}(t) &= \frac{\kappa_{j \rightarrow n,p}}{2 - \delta_{n,p}} \mathcal{I}_{i \rightarrow j}(t) \\ &\quad - \sum_o (\sigma_{n \rightarrow o} J(t) + \Gamma_{n \rightarrow o}) \mathcal{I}_{i \rightarrow j \rightarrow n}(t), \end{aligned} \quad (27)$$

$$\begin{aligned} \frac{d}{dt}\mathcal{I}_{i \rightarrow m \rightarrow n}(t) &= (\sigma_{m \rightarrow n} J(t) + \Gamma_{m \rightarrow n}) \mathcal{I}_{i \rightarrow m}(t) \\ &\quad - \sum_o (\sigma_{n \rightarrow o} J(t) + \Gamma_{n \rightarrow o}) \mathcal{I}_{i \rightarrow m \rightarrow n}(t). \end{aligned} \quad (28)$$

The indices  $i, j, k$  and  $l$  refer to molecular states whereas the indices  $m, n$  and  $o$  refer to atomic states. Eqn (26) computes molecular pathway populations, eqn (27) computes pathway populations where the final state is an atomic one, but the previous states were molecular. Pathway populations where the final and the previous states are atomic ones are computed using eqn (28). Solving eqn (26)–(28), allows us to register all energetically-allowed pathways.

## B Direct and exchange coefficients

In the Hartree–Fock framework, after applying the variational principle,<sup>38</sup> the electron–electron interaction terms can be written as

$$\sum_1^{\text{orbs}} a_i J_i \phi_e - \sum_1^{\text{orbs}} b_i K_i \phi_e = \varepsilon^{\text{ee}} \phi_e, \quad (29)$$

where  $\phi_e$  is the spin-orbital of the molecular continuum electron with spin orientation  $\mu_e$  and  $\varepsilon^{\text{ee}}$  is the energy contribution of the electron–electron interaction terms. The index  $i$  refers to a bound molecular orbital and  $J_i$  and  $K_i$  are defined as

$$J_i \phi_e = \left\langle \phi_i \left| \frac{1}{r_{12}} \right| \phi_i \right\rangle \phi_e, \quad (30)$$

$$K_i \phi_e = \left\langle \phi_i \left| \frac{1}{r_{12}} \right| \phi_e \right\rangle \phi_i.$$

To obtain the  $a_i$  and  $b_i$  coefficients in the general case, it suffices to obtain  $a_i$  and  $b_i$  for three limiting cases. Since we consider molecular orbitals in all three limiting cases, the electron occupancy of the shells involved is zero, one or two. If a shell is not occupied, the coefficients  $a_i$  and  $b_i$  are zero. For the first limiting case, a two-electron system is considered, with both electrons initially occupying a single shell  $i$  and one of these electrons finally being emitted to the continuum. Spin is conserved and it is equal to zero in the initial and final states. Therefore, a two-electron wavefunction must be constructed that is anti-symmetric in spin and anti-symmetric under exchange of electrons. Such a wavefunction is given as a sum of the following two Slater determinants

$$\Phi(q_1, q_2) = \frac{1}{\sqrt{2}} \left( \frac{1}{\sqrt{2!}} \begin{vmatrix} \phi_i^\uparrow(q_1) & \phi_e^\downarrow(q_1) \\ \phi_i^\uparrow(q_2) & \phi_e^\downarrow(q_2) \end{vmatrix} - \frac{1}{\sqrt{2!}} \begin{vmatrix} \phi_i^\downarrow(q_1) & \phi_e^\uparrow(q_1) \\ \phi_i^\downarrow(q_2) & \phi_e^\uparrow(q_2) \end{vmatrix} \right), \quad (31)$$

where  $q_1$  and  $q_2$  are the spin and space coordinates of the two electrons. Using spin conservation and exchange symmetry, it is found that the energy contribution of the electron–electron interaction term is given by

$$\varepsilon^{\text{ee}} = \left\langle \Phi \left| \frac{1}{r_{12}} \right| \Phi \right\rangle = \left\langle \phi_i \phi_e \left| \frac{1}{r_{12}} \right| \phi_i \phi_e \right\rangle + \left\langle \phi_i \phi_e \left| \frac{1}{r_{12}} \right| \phi_e \phi_i \right\rangle. \quad (32)$$

Using the variational principle in the Hartree–Fock equations scheme<sup>38</sup> for the continuum orbital, the following equations are obtained

$$J_i \phi_e + K_i \phi_e = \varepsilon^{\text{ee}} \phi_e. \quad (33)$$

Comparing eqn (29) and (33), we find that  $a_i = 1$  and  $b_i = -1$ .

Another limiting case involves two shells  $i$  and  $j$ . In the initial state one electron is in shell  $i$  and two electrons occupy shell  $j$ .

In the final state one electron from the  $j$  shell escapes to the continuum. A three-electron wavefunction must be constructed which is anti-symmetric in spin regarding the continuum electron and the electron in the  $j$  shell and anti-symmetric under exchange of electrons. Such a wavefunction is given as a sum of the following two Slater determinants

$$\Phi(q_1, q_2, q_3) = \frac{1}{\sqrt{2 \times 3!}} \begin{vmatrix} \phi_i^\uparrow(q_1) & \phi_j^\downarrow(q_1) & \phi_e^\uparrow(q_1) \\ \phi_i^\uparrow(q_2) & \phi_j^\downarrow(q_2) & \phi_e^\uparrow(q_2) \\ \phi_i^\uparrow(q_3) & \phi_j^\downarrow(q_3) & \phi_e^\uparrow(q_3) \end{vmatrix} \quad (34)$$

$$- \frac{1}{\sqrt{2 \times 3!}} \begin{vmatrix} \phi_i^\uparrow(q_1) & \phi_j^\uparrow(q_1) & \phi_e^\downarrow(q_1) \\ \phi_i^\uparrow(q_2) & \phi_j^\uparrow(q_2) & \phi_e^\downarrow(q_2) \\ \phi_i^\uparrow(q_3) & \phi_j^\uparrow(q_3) & \phi_e^\downarrow(q_3) \end{vmatrix}.$$

Following the same procedure as for the other limiting case, the following equations are obtained

$$\left( J_i - \frac{1}{2} K_i + J_j + K_j \right) \phi_e = \varepsilon^{\text{ee}} \phi_e, \quad (35)$$

Comparing eqn (29) and (35), it is found that  $a_j = 1$  and  $b_j = -1$ , while  $a_i = 1$  and  $b_i = \frac{1}{2}$ .

The third limiting case involves two electrons occupying shell  $i$  and two electrons occupying shell  $j$  in the initial state, with one electron from orbital  $j$  escaping to the continuum in the final state. Following the same procedure as in the other two cases, it can be shown that  $a_i = 2$  and  $b_i = 1$  and  $a_j = 1$  and  $b_j = -1$ . In general, for all molecular ion states, in the Hartree–Fock formalism, the occupation coefficients  $a_i$  and  $b_i$  can be obtained using the above three limiting cases.

## Acknowledgements

A. E. is grateful to Peter Lambropoulos for pointing out DCH formation as an interesting problem in molecules interacting with FEL pulses. A. E. acknowledges the use of the Legion computational resources at UCL.
